

# Binomial Inference

Pedro Victor Brasil Ribeiro

2021-12-19 - Last changed in 2021-12-24

Suppose you have a sample that comes from a binomial distribution, and the sample size is equal to  $m$ . How can you estimate the parameter  $p$  and  $n$  With only that sample?

To solve this problem we use a estimator deriving from the likelihood function, which is define as:

$$L(x; \theta) = \prod_{i=1}^n f(x_i; \theta) \quad (1)$$

And then we find the maximum point of the function, or in other words, the point that make the derivative of  $f(x; \theta)$  igual to 0.

## The Problem

Let  $X_1, X_2, \dots, X_m$  be a random variable i.i.d. (Independent and identically distributed) a binomial sample of  $m$  observations with parameters  $n$  and  $p$ , in other words  $X \sim \text{Bin}(n, p)$ . Then we know that the density function of a binomial is:

$$f(x; \{n, p\}) = \binom{n}{x} p^x (1-p)^{n-x}; \quad n \in \mathbb{Z}^* \quad p \in (0, 1) \quad (2)$$

So first of all we need to find the likelihood function for a binomial distribution so using the equation 1, where  $f(x; \theta)$  for  $\theta = \{n, p\}$ , expressed in the equation 2.

## Estimation

Usually is more convenient to work with the derivative of  $\log[L(x; \theta)]$ , note that the maximum point of  $L(x; \theta)$  and  $\log[L(x; \theta)]$  is the same point.

$$\begin{aligned} L(x; \theta) &= \prod_{i=1}^n f(x_i; \theta) \\ &= \prod_{i=1}^n \binom{n}{x_i} p^{x_i} (1-p)^{n-x_i} \\ \Rightarrow l(x; \theta) &= \sum_{i=1}^m \log \left[ \binom{n}{x_i} \right] + \sum_{i=1}^m x_i \log(p) + \sum_{i=1}^m (n - x_i) \log(1-p) \\ &= \sum_{i=1}^m \log \left[ \binom{n}{x_i} \right] + m\bar{X} \log(p) + (mn - m\bar{X}) \log(1-p) \end{aligned}$$

## Estimate p, with n known

Supposing that the parameter n is known, in order to estimate the parameter p we can derive  $l(x; \theta)$  in relation to p. We have:

$$\begin{aligned} \frac{\partial l(x; \theta)}{\partial p} &= \frac{\partial}{\partial p} \left[ \sum_{i=1}^m \log \left[ \binom{n}{x_i} \right] + m\bar{X} \log(p) + (mn - m\bar{X}) \log(1 - p) \right] \\ &\Rightarrow \frac{\bar{X}}{\hat{p}} - \frac{n - \bar{X}}{1 - \hat{p}} = 0 \end{aligned} \quad (3)$$

There's no explicit formula for the estimator of p, so we need to use some computational way to find the maximum root of the derivative of  $l(x; \theta)$ . A very good way of doing it is known as the Newton-Raphson Method, there are more ways to solve the problem, such as the secant method, Bisection method or even finding the maximum point of the likelihood function (which will be done in the last section). In this document we will use the Newton-Raphson method.

## Newton-Raphson method

Newton-Raphson method is an iterative equation that starts with an initial guess of the root. The Newton-Raphson method is an approach to find the roots of non-linear equations, is a well-known and widely used for its simplicity and its speed for convergence.

In this document we will not explain the theory behind the method, but the image below is a pretty good way to have a hint on how it works. Basically, given a start point (first guess), is calculated the derivative, so is found the point where the tangent line "touches" the x-axis, then is calculated its image on the y-axis and the derivative on the point, and so on. Until in one time the difference on the two points is lower than the tolerance accepted for the user.

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)} \quad (4)$$

The code used to find the root using the Newton-Raphson method were made by Aaron Schlegel on the [LINK](#), as it follows:

```
## Newton-Raphson

newton.raphson <- function(f, a, b, tol = 1e-5, n = 1000) {
  require(numDeriv) # Package for computing f'(x)

  x0 <- a # Set start value to supplied lower bound
  k <- n # Initialize for iteration results

  # Check the upper and lower bounds to see if approximations result in 0
  fa <- f(a)
  if (fa == 0.0) {
    return(a)
  }

  fb <- f(b)
  if (fb == 0.0) {
    return(b)
  }

  for (i in 1:n) {
    dx <- genD(func = f, x = x0)$D[1] # First-order derivative f'(x0)
    x1 <- x0 - (f(x0) / dx) # Calculate next value x1
    k[i] <- x1 # Store x1
    # Once the difference between x0 and x1 becomes sufficiently small, output the results.
    if (abs(x1 - x0) < tol) {
      root.approx <- tail(k, n=1)
      res <- list('root_approximation' = root.approx, 'iterations' = k)
      return(res)
    }
    # If Newton-Raphson has not yet reached convergence set x1 as x0 and continue
    x0 <- x1
  }
  print('Too many iterations in method')
}
```

So let the parameter as previously defined ( $n = 17$ ,  $p = 0.75$ ), we will define the function 3 on hat and run the newton raphson method as shown in the equation 4.

So for the seed 18122021 we had a estimation on the p-value 0.7392513 and the root converged with 13, such that the tolerance was of 0.00001.

To confirm the efficiency of the estimator we will use a Monte-Carlo simulation, which basically means, that we will the code a bunch of times and see the estimator behavior. In this case we will run the code 10,000 times, and for we have the same result.

From the plot above we can see that the estimations are highly concentrated inside the interval of confidence (blue line). To check the coverage of the estimation, we can see the percentage of points that are inside the interval and the value has to be greater than or equal to the confidence chosen ( $\gamma = 0.95$ ).

Let's call "hit" the points that are within the confidence interval and "error" the ones that aren't.

coverage	n
error	0.048
hit	0.952

So, since the value is equal to 0.952, which is greater than the chosen  $\gamma$ , then the estimator has a good coverage, and the value converges quickly, with only 13 or 14 interactions (12.34% and 87.66%, respectively). So we have a great estimator.

### Estimate n, with p known

Now we will use the same theory to find the estimate for n, called  $\hat{n}$ , so first of all we will open the binomial on the log of the likelihood function:

$$\begin{aligned}
l(x; \theta) &= \sum_{i=1}^n \log \left[ \frac{n!}{(n-x_i)!x_i!} \right] + n\bar{X} \log(p) + (mn - m\bar{X}) \log(1-p) \\
&= \sum_{i=1}^n \log(n!) - \sum_{i=1}^n \log[(n-x_i)!] - \sum_{i=1}^n \log(x_i!) + n\bar{X} \log(p) + (mn - m\bar{X}) \log(1-p) \quad (5)
\end{aligned}$$

One thing that we have to note is that “n” is a discrete number, therefore the function 5 doesn’t have a derivative on respect to n, but we have a very interesting function that can help to solve this problem, that function is the gamma function.

$$\Gamma(t) = \int_0^{\infty} x^{t-1} e^{-x} dx \quad (6)$$

The gamma function have a very interesting propriety:

- $\Gamma(n) = (n-1)! \Rightarrow n! = \Gamma(n+1).$

Which is a continuous function. So making the substitution of the equation 6 in the equation 5, and defining that the derivative of  $\log[\Gamma(n)]$  in relation to n is equal to  $\psi^{(0)}(n)$ .

$$l(x; \theta) = \sum_{i=1}^n \log(n!) - \sum_{i=1}^n \log[(n-x_i)!] - \sum_{i=1}^n \log(x_i!) + n\bar{X}\log(p) + (mn - m\bar{X})\log(1-p)$$

$$\frac{\partial l(x; \theta)}{\partial n} = m\psi^{(0)}(n+1) - \sum_{i=1}^n \psi^{(0)}(n-x_i+1) + m\log(1-p)$$

Then the maximum likelihood for n doesn’t have a closed equation, similar to p. So we have the function.

$$m\psi^{(0)}(\hat{n}+1) - \sum_{i=1}^n \psi^{(0)}(\hat{n}-x_i+1) + m\log(1-p) = 0 \quad (7)$$

**Both n and p unknow**
